# 1 Introduction

Most high performance computing systems are a connected cluster of inexpensive computers. These computers collectively solve computationally intensive problems, e.g. weather prediction. This distributed memory model allows for processors to run identical or different programs, each working on different chunks of problem/ data. This provides scalability: adding more processors to the system adds more units of computation. However, as there is no global memory for all processors, exchanging data becomes necessary, say near the borders of the data chunks. This communication is done explicitly through Message Passing Interface or MPI. Routines include Point-to-Point messages, collective messages, synchronization, etc. These routines are complex and programmers are required to learn the function signatures and the various parameters required. M<sub>AP</sub>Reduce for Stampede is a C++ library that provides an abstraction for programmers to focus on solving the problem rather than worry about the underlying communications among the processors. MARS is an abstraction over Boost.MPI which itself is an abstraction over MPI.

## 1.1 MapReduce

MapReduce is a programming paradigm that enables developers to take advantage of clusters that make the same operations on each element in a given dataset. With MapReduce, a developer can distribute data easily and apply the same computations without having to worry about the actual maintenance or synchronization. For our project, we decided to build a MapReduce API for C++. As the end result, the developers will only need to know how to formulate their algorithm and our API will handle the actual distribution of the data and the ending reduction.

## 1.2 Boost.MPI

Boost.MPI is a library for message passing in high-performance parallel applications. Unlike communication in threaded environments or using a shared-memory library, Boost.MPI processes can be spread across many different machines, possibly with different operating systems and underlying architectures. It is a C++-friendly interface to the standard Message Passing Interface (MPI), the most popular library interface for high-performance, distributed computing. This library provides an interface to MPI that better supports modern C++ development styles, including complete support for user-defined data types and C++ Standard Library types.

## 1.3 Problem

Although Boost.MPI provides a good abstraction, it still involves knowing MPI.

## 2 Setup

### 2.1 Constraints

Given that we know that the MapReduce API will be used so that the developer only needs to focus on formulating their algorithm instead of handling synchronization between processors, we had to make sure the MapReduce handled it for the developer. Since our API is meant for C++ developers, we used MPICH-2 (MPI) in order to maintain the computations across nodes within a cluster. As developers of the API we constrained the expectations of those who use this library to be able to write the actual computation that they would like to see on their data. For example, given a large list of numbers of size "n", the developer should understand what computation they want to be done on each element of the list.

### 2.2 Modeling MapReduce

Our project, although universal, was designed to work with the Stampede Supercomputer Cluster. Earlier we stated that our MapReduce API will handle the distribution of data across multiple processes. To show how this is possible, let's list out a few definitions.

- Master: A process that initially distributes the data and gathers the output after all the computations have completed
- Mapper: A set of processors which apply the user defined computation on the elements of the dataset. The Mapper returns a tuple of the key (the unique element in the dataset) and a value (occurrence, count, etc.).
- Reducer: A set of processors which reduce the tuples defined in Mapper and applies the user defined function that specifies how to reduce or combine the individually mapped out data. After reducing all the values associated with the common keys, the Reducer processes send the data back to Master, which then outputs the result.

### 2.3 Formulation

In order to use this API, we modeled the library such that the user needs to define the Mapper and Reducer. Assuming that the computation is the same on every element of the dataset, the Master process is what decides how to split the dataset to the rest of the processes. For this piece of the project we could not assume that each process will be given a single element in the dataset, otherwise the number of processes will be the size of the dataset, which is impossible to have.

The Master process lets the user define how the dataset should be split. Furthermore, because we are assuming the computation on each element of the dataset is the same or independent, the user will define the `map()` function within the Mapper class. The `map()` function returns tuples of key (the element of the dataset) and the value, which is the value after applying the `map()` function. The user will also define the `reduce()` function within the Reducer class, which takes in each of the common keys and applies the `reduce()` function to congregate all the values to return a single key value pair.

The Mapper class contains the `map()` function, which we assume applies a computation

that is uniform across each element of the dataset. Essentially, if the data is a list [1, 2, 3, 4], then the map() function could just add 1 to each element. The output key value pairs of the map() function could look like this [(1, 2), (2, 3), (3, 4), (4, 5)] where the value is the given element of the dataset incremented by one. Notice how because each computation is independent, we can distribute the data and let the map() function run in parallel across processes in Stampede.

The Reducer class contains the reduce() function, which takes in a list of common key value pairs, where the key is common, and then applies reduce() in order to aggregate the list of values into one single value. This new key value pair is then sent back to Master, who then handles how to output the result. Assume that you have a key value pairs list (key, [v1, v2 v3]), reduce() will return a (key, finalValue) and broadcast that back to Master.

### 3 Usage

The classic example is to show how to use our MapReduce API in order to get a character count from a set of strings. Let's say that you have the String:

```
"Hey how is it going"
```

Our end result should look like:

```
e 1
g 2
h 2
i 3
n 1
o 1
s 1
t 1
w 1
y 1
```

In order to properly use this API, the user needs to define the Master class, the map() function in Mapper, and reduce() within Reducer. To make computations easier, we already split up the data for the user, but it is still helpful to look at a sample formulation:

```
class CharCountMapper : public Mapper<MK, MV, RK, RV> {

    virtual vector<RPAIR> map(vector<MPAIR> tuples) {
        return tuples;
    }
};

class CharCountReducer : public Reducer<RK, RV> {

    virtual RPAIR reduce(RK key, vector<RV> values) {
        RV sum = 0;
```

```

        for (int i = 0; i < values.size(); ++i) {
            sum += values[i];
        }
        return RPAIR(key, sum);
    }
};

```

Since we have already split up the tuples in the data set, which is a string, our `map()` function will just output a character key and the initial value as 1. We use 1 as the default value because naturally that starting count number given an occurrence. After the `map()` function is applied to every item in the dataset, Master will go ahead and create a new pair such that all the common keys value pairs will be passed into `reduce()` as a single key and a list of values. `reduce()` in our case will taken in a key and list of values pair, sum up the occurrences, which is the list of values and then sends the final result back to Master.

## 4 Assumptions

RK needs to be hashable. Enhancement: requires data to fit on one processors (master) which is sent to various workers.

## 5 Performance

Boost.MPI performance. And performance of apps written wit

## 6 Conclusion

MARS provides an abstraction where the programmer is unaware of the underlying complexity of making MPI function calls. Issue with a single master. Done done done.
